DEVELOPMENT OF METHODS FOR FIELD DISTRIBUTION OF EGGS OF THE INSECT PREDATOR

Chrysopa carnea Stephens

By S. L. Jones and R. L. Ridgway¹

ABSTRACT

Experiments were conducted to select materials for spraying and sticking the eggs of *Chrysopa carnea* Stephens on cotton plants, to study the fate of these eggs on plants and soil, and to evaluate different methods for distributing the eggs. Various materials were tested for their egg-suspending ability by agitating a 50-ml solution of each with 50 *C. carnea* eggs in a graduated cylinder and observing the mixtures; also, the eggs were later checked for hatch. *C. carnea* eggs were placed on soil at different distances from cotton plants and observed daily for hatch, and the plants were inspected for larvae. The effects of wind velocities of 5, 10, and 15 mi/h on egg adherence to plants was determined with a specially constructed wind tunnel and fan. Egg survival was determined after distribution of eggs with a screened "shaker" and nozzle sprayers on a flat surface in the laboratory and on cotton plants in the field at a rate equal to 100,000 eggs per acre. Results indicated that water containing 0.125 percent agar was the preferred spray medium and that the action of wind and rain greatly affected egg adherence to plants. Consequently, the techniques developed are apparently not adequate to insure high levels of egg survival in the field, particularly under adverse conditions.

INTRODUCTION

Supplemental releases of the insect-predator *Chrysopa carnea* Stephens have been successfully utilized in field and field-cage experiments to suppress populations of the bollworm, *Heliothis zea* (Boddie), and the tobacco budworm, *Heliothis virescens* (F.) (3, 5, 6, 9).² *C. carnea*

were manually released in these experiments primarily in the larval stage, although used successfully in two field

Promising results from demonstrated the need suitable automated method larger numbers of *C. carnea* cannibalistic nature of *C. carnea* sticking the eggs provides a Other researchers have for distributing insect eggs et al. (7) explored method spraying the eggs of *C. carnea* L., *C. transversoguttata* *C. carnea* spp. and reported survival ever, a rather high percentage

lost from potato foliage in the field. Thewke and Puttler (8) described a method for spraying eggs of the cabbage looper, *Trichoplusia ni* (Hübner), and the Angoumois grain moth, *Sitotroga cerealella* (Olivier), to measure parasitization by *Trichogramma* spp., and Nordlund et al. (4) described a method for field application of *Heliothis zea* eggs.

In order to expand research on supplemental releases of *C. carnea* eggs for control of the bollworm and tobacco budworm on cotton, experiments were conducted to develop methods for field distribution of these eggs. This report presents the procedures and results of these experiments.

EXPERIMENTAL PROCEDURES AND RESULTS

Egg-Suspending Agents

An initial laboratory experiment was conducted to evaluate several materials for suspending *C. carnea* eggs in water. Materials investigated were Methocel³ (methyl cellulose preparation, Dow Chemical Co.), Dacagin (thickening agent, Diamond-Shamrock, Inc.), Dacagin plus sucrose, corn starch plus sucrose, sucrose, and agar.

The suspending agents were dissolved in water, using heat when required. These solutions were tested for their suspending ability by agitating 50 ml of each with 50 *C. carnea* eggs in a graduated cylinder. The mixtures were then observed periodically for 1 hour for egg-suspension results. The eggs were then removed, held individually, and observed for hatch. Untreated eggs from the original egg lot were used as a control.

Dacagin (0.05 or 0.125 percent), Dacagin (0.5 percent) plus sucrose (10 percent), and agar (0.125 percent) suspended eggs and caused only a slight reduction (zero to 14 percent) in egg hatch (table 1). Although Methocel (0.7 percent) and corn starch plus sucrose satisfactorily suspended eggs, they also greatly reduced egg hatch.

TABLE 1.—Results of suspending *Chrysopa carnea* eggs in various water solutions and the effects on egg hatch

Solution	No. minutes 90 percent of eggs were suspended	No. eggs observed for hatch	Percent reduction in hatch
Corn starch (0.5 pct), sucrose (13.0 pct)	>60	50	94
Corn starch (1.0 pct), sucrose (11.5 pct)	>60	50	94
Corn starch (2.0 pct), sucrose (10.0 pct)	>60	50	84
Water only (control)	25	0
Sucrose (5 pct)	1.5
Sucrose (10 pct)	4
Sucrose (12 pct)	8	150	20
Sucrose (15 pct)	3
Sucrose (20 pct)	3
Dacagin (0.125 pct)	5
Dacagin (0.025 pct)	15
Dacagin (0.05 pct)	>60	600	14
Dacagin (0.5 pct)	>60
Dacagin (0.5 pct), sucrose (10 pct)	>60	700	11
Methocel (0.5 pct)	>60
Methocel (0.7 pct)	>60	50	91
Agar (0.125 pct)	>60	200	0

Egg Survival on Soil and Plants

Before conducting experiments specifically designed to evaluate methods of distribution, experiments were conducted to provide some understanding of the survival of *C. carnea* eggs placed on soil and to study the effects of wind velocity on the adherence of eggs to cotton foliage.

For the soil experiment, two soil types (coarse sand and fine sandy loam) were placed adjacent to cotton plants growing in the greenhouse. The soil was placed 1.5 inches deep in trays 3.3 by 4 by 0.16 feet in size. Potted plants (six per tray) protruded through small holes in the center of the tray. Stikem was used to ring the outside of the trays so the *C. carnea* larvae could not escape. *C. carnea* eggs were then placed (1) at the base (centerline of row) of the plants (24 eggs), (2) 10 inches from the base (12 eggs on each side of row), and (3) 20 inches from the base (12 eggs on each side of row). The eggs were placed on 0.75-inch-diameter disks of filter paper that were in turn placed on the soil to make it possible to find the eggs

or egg shells. The eggs were observed daily for hatch, and the plants were inspected daily for *C. carnea* larvae.

Results show that 52.8 to 77.8 percent of the larvae hatched from eggs placed on the soil were able to ascend onto the plants (table 2). Although the surviving larvae were from eggs placed on soil where temperatures were 70° to 90° F, survival could be expected to be much lower at higher temperatures (1).

For the wind experiment, a wind tunnel (2 by 3 by 10 feet) was constructed. The bottom and sides of the tunnel were plywood, and the top was glass. Wind velocity was regulated by external louvers on the fan intake. Three replicates of 12 plants (each plant was sprayed with an average of four eggs in water and 0.125 percent agar) were exposed to wind velocities of 5, 10, and 15 mi/h for 24 hours. The plants were examined for eggs after 15 and 24 hours of exposure.

TABLE 2.—*Survival of Chrysopa carnea after distribution of eggs on soil at different distances from cotton plants*

Soil ¹ and distance	Total No. eggs	Percent hatch	Percent larval recovery ²
Sand, zero inches	120	90.0	77.8
Sand, 10 inches	120	80.0	68.3
Sand, 20 inches	264	84.2	58.6
Loam, 20 inches	144	88.9	52.8

¹ Coarse sand and fine sandy loam; temperature of soil ranged from 70° to 90° F.

² Based on number of eggs hatched.

Wind substantially decreased egg recovery, although little difference between wind velocities was detected (table 3).

Egg-Distributing Methods

Three experiments were conducted to evaluate methods of distributing *C. carnea* eggs. In the first experiment, *C. carnea* eggs were distributed in the laboratory on a flat, 25- by 3-foot strip of paper. Known volumes of the various suspending mixtures were distributed at a rate equal to 100,000 eggs per acre. Rice hulls, on which eggs had been oviposited, were distributed with a "shaker" made from a ½-pint container covered with a ¼- by ¼-inch-mesh metal screen. Eggs mixed with corn cob granules (16/30 mesh) and eggs only were distributed in a similar

manner with an 8-dr shell vial covered with a 20- by 20-mesh plastic screen. Eggs were also sprayed (from a height of 18 inches at a speed of 1.2 mi/h) in a solution of water and Dacagin (0.125 percent) at 2.5 lb/in² through a nozzle similar to that designed by Gast (2) for spraying boll weevil (*Anthonomus grandis* Boheman) eggs on artificial diet. The number of eggs per linear foot of paper was then recorded (table 4).

All these methods provide a potentially satisfactory method of distributing eggs. However, the application of eggs alone resulted in uneven distribution.

A second experiment was conducted in the field to evaluate the methods studied in the laboratory. The same methods were used to distribute *C. carnea* eggs on cotton plants in single row plots 25 feet long. The number of eggs on plants was recorded 12 to 24 hours later. Also, the plants were examined for *C. carnea* larvae 7 and 10 days after the eggs were distributed.

TABLE 3.—*Recovery of Chrysopa carnea eggs sprayed on cotton plants and exposed to different wind velocities¹*

Wind (mi/h)	Total No. eggs	Percentage recovery after—	
		15 hours	24 hours
0	192	99.5	98.5
5	192	86.5	79.7
10	144	92.4	85.4
15	144	85.4	77.1

¹ Eggs in water containing 0.125 percent agar sprayed on 18-inch-tall cotton plants.

Agar in water provided the best recovery (47.9 percent) of eggs tested (table 4). The recovery was highly desirable during the counting period, as time elapsed. The eggs seemed to interfere with the recovery of the eggs to the plants 7 and 10 days later. To find significant differences (less than 5 percent)

For the third experiment, a 2-row experiment was conducted to further explore the use of eggs. A complete container for holding and suspending or

¹ Only eggs found on plants were recorded in the field.

eggs) were connected to two nozzles (one for each row) similar to those used in the first two experiments. Potted cotton plants 2 to 3 feet tall (arranged outdoors in two 40-inch rows) were sprayed at a rate equal to 6 gal of water (with 0.125-percent agar) and 100,000 eggs per acre.

Immediately after spraying, the plants were examined for *C. carnea* eggs, and 69 percent of the eggs sprayed were recovered from the plants. Heavy rains that followed within 24 hours apparently washed the eggs from the plants and thus prevented hatch and survival.

CONCLUSIONS

These studies have provided useful information for developing satisfactory methods of distributing *C. carnea* eggs. An improved sticker and further studies on the fate of *C. carnea* eggs in the field should provide the basis for developing improved methods for distributing eggs in the field. However, until significant improvements are made, the release of *C. carnea* larvae apparently will provide the most dependable results.
